C# and VB.net will create a .exe file from the program. The .exe will contain the program, encrypted, and it will have a password to decrypt it. While this is not bulletproof, it is usually good enough. For a lot of languages, if they can create an .exe, they can usually read the entire binary file and decompress it. So now that you have a decrypted file, you can read it and perform your calculations. If you are lucky, the program just runs. If the program has any other ways to run, those could be exploitable, too. An example of a program with hidden payloads: This one also contains a program to decrypt the binary using keys that are also stored in memory. It will create a file named win-7xv1db73f03-1b2e-4b22-b1c5-4938f74efb3c-1.exe And you would have to run that program to access the binary file.

A: Most modern programming languages use some sort of encryption, and can make use of public-key cryptography, which allows anyone to encrypt the code in a way that you (and only you) have access to. Such code can be stored on-disk in some format like ZIP or tar.gz (which is basically a zip archive with a GZIP header, giving it properties of both), and if you're lucky, you might be able to extract the code from within that archive file. If you can extract the code, and you have a good idea what language and what kind of libraries were used, there are a few options you have for decryption. If the encryption used was DES or 3DES, you should be able to read the output using either the original key or a copy of the original key. If it was AES-128 or AES-256, then you need to use a copy of the original key. If the encryption used is Rijndael, you can read it using a program like John the Ripper. You'll need to run it against the decryption key. I have no idea how to find a copy 82157476af
